Short communication

Mathematical modeling of a lithium ion battery with thermal effects in COMSOL Inc. Multiphysics (MP) software

Long Cai, Ralph E. White *

Department of Chemical Engineering, University of South Carolina, 301 Main Street, Columbia, SC 29208, United States

1. Introduction

The existing lithium ion battery model in COSMOL Inc. Multiphysics 3.5a is extended here by adding an energy balance and the temperature dependence of properties of the battery. This thermal model is developed based on the pseudo two-dimensional (P2D) model which was described in [1,2] and a thermal, electrochemistry coupled model. The diffusion coefficient of Li ions in the solid phase and electrolyte, the reaction rate constants of the electrochemical reactions, the open circuit potentials and the thermal conductivity of the binary electrolyte depend on the temperature in the model presented here.

2. Mathematical model

A schematic of a lithium ion battery is shown in Fig. 1. Generally, a lithium ion battery consists of the current collector, the positive electrode, the separator and the negative electrode. A lithiated organic solution fills the porous components and serves as the electrolyte.

The material balance for the Li ions in an active solid material particle is governed by Fick’s second law in spherical coordinates:

$$\frac{\partial c_{s,i}}{\partial t} = D_{s,i} \frac{1}{r^2} \frac{\partial}{\partial r} \left( r^2 \frac{\partial c_{s,i}}{\partial r} \right) \tag{1}$$

where \(i = p\) for the positive electrode and \(i = n\) for the negative electrode. At the center of the particle, there is no flux, that is:

at \(r = 0\) : \(-D_{s,i} \frac{\partial c_{s,i}}{\partial r} = 0\)

On the surface of the particle, the flux is equal to the consuming/producing rate of Li ions due to the electrochemical reaction occurring at the solid/liquid interface:

at \(r = R_{s,i}\) : \(-D_{s,i} \frac{\partial c_{s,i}}{\partial r} = J_i\)

where \(J_i\) is the flux of lithium ions away from the surface of the spherical particles.

The material balance for the binary electrolyte in the liquid phase is given by:

$$\varepsilon_i \frac{\partial c_i}{\partial t} = \frac{\partial}{\partial x} \left( D_{\text{eff},i} \frac{\partial c_i}{\partial x} \right) + (1 - t_0) J_i \tag{2}$$

where \(i = p, s,\) and \(n\) and \(q_i\) is the electrode surface area per unit volume of the electrode. In the separator the pore wall flux \(J_s\) is equal to zero. At the two ends of the cell in the x-direction, there is no mass flux, that is:

$$-D_{\text{eff},p} \frac{\partial c_p}{\partial x} \bigg|_{x=0} = 0$$

$$-D_{\text{eff},n} \frac{\partial c_n}{\partial x} \bigg|_{x=L_p+L_s+L_n} = 0$$

At the interfaces between the positive electrode/separator and separator/negative electrode, the concentration of the binary...
electrolyte and its flux are continuous

$$
\begin{align*}
\text{at} & \quad x=L_p, \\
\frac{\partial C_i}{\partial x} |_{x=L_p} & = 0, \\
\frac{\partial C_i}{\partial x} |_{x=L_s} & = 0, \\
\frac{\partial C_i}{\partial x} |_{x=L_s+L_p+L_s+L_p} & = 0.
\end{align*}
$$

The effective diffusion coefficient of the binary electrolyte in the liquid phase is corrected by porosity:

$$D_{\text{eff},i} = D_{i,\text{brugg}}$$

where the diffusion coefficient of the binary electrolyte ($D_{i,\text{brugg}}$) is given in Ref. [3] as follows:

$$D_{i,\text{brugg}} = 10^{-4} \times 10^{-4.43\cdot(54/(T-229.5\cdot10^{-3}c_i))-0.22\cdot10^{-7}c_i}$$

(3)

The charge balance in the solid phase is governed by Ohm’s law:

$$\sigma_{\text{eff},i} \frac{\partial \phi_i}{\partial x} |_{x=0} = \text{I}_{\text{app}}$$

(4)

where $i=p$ and $n$. The effective conductivity is determined by $\sigma_{\text{eff},i} = \sigma_i(1 - \epsilon_i - \epsilon_f)$, where $\sigma_i$ is the specific area calculated by $\sigma_i = (3/R_{\text{p}})(1 - \epsilon_i - \epsilon_f)$. At the interface of the current collector and the positive electrode, the charge flux is equal to the current density applied to the cell:

$$\sigma_{\text{eff},p} \frac{\partial \phi_{1,p}}{\partial x} |_{x=0} = \text{I}_{\text{app}}$$

At the interfaces of the positive electrode/separator and the separator/negative electrode, there is no charge flux:

$$\sigma_{\text{eff},p} \frac{\partial \phi_{1,p}}{\partial x} |_{x=L_p} = 0$$

$$\sigma_{\text{eff},n} \frac{\partial \phi_{1,n}}{\partial x} |_{x=L_p+L_s} = 0$$

The potential of the solid phase at the right end of the cell is set to zero $\phi_{1,n}|_{x=L_p+L_s+L_s+L_p} = 0$, and the potential of the solid phase at $x=0$, $\phi_{1,n}|_{x=0}$, is equal to $\varepsilon_{\text{cell}}$ (the cell voltage).

The charge balance in the liquid phase is based on Ohm’s law and is given by:

$$-\frac{\partial}{\partial x} \left( \kappa_{\text{eff},i} \frac{\partial \phi_{1,i}}{\partial x} \right) + \frac{2RT(1 - \epsilon_i)}{F} \frac{\partial}{\partial x} \left( \kappa_{\text{eff},i} \frac{\partial \ln(c_i)}{\partial x} \right) = a_F \ell_i$$

(5)

where $i=p, s$ and $n$ and the specific conductivity of the binary electrolyte is a function of temperature and the concentration of the binary electrolyte in the liquid phase:

$$\kappa_{\text{eff},i} = \kappa_i \ell_i$$

where the expression of the ionic conductivity for the binary electrolyte is given in Ref. [3] as follows:

$$\kappa_i = 10^{-4} \times 10^{-4}\cdot(54/(T-229.5\cdot10^{-3}c_i))-0.22\cdot10^{-7}c_i$$

(6)

At the two ends of the cell, there is no charge flux in the liquid phase:

$$-\kappa_{\text{eff},p} \frac{\partial \phi_{2,p}}{\partial x} |_{x=0} = 0$$

and

$$-\kappa_{\text{eff},n} \frac{\partial \phi_{2,n}}{\partial x} |_{x=L_p+L_s+L_p} = 0$$

The potential in the solution phase and its flux are continuous at the interfaces of the electrodes and the separator.
In the above equations the pore wall flux, \( J_i \), is determined by the Bulter–Volmer equation:

\[
J_i = k_i (c_{s,i,max} - c_{s,i,surf})^{0.5} c_{s,i,surf}^{-0.5} \exp \left( \frac{0.5F}{RT} \eta_i \right) - \exp \left( \frac{0.5F}{RT} \eta_i \right)
\]

and the overpotential of the intercalation reaction is given by:

\[
\eta_i = \phi_{1,i} - \phi_{2,i} - U_i
\]

The energy balance is given by [4,5]:

\[
\rho C_p \frac{dT}{dt} = \lambda \frac{\partial^2 T}{\partial x^2} + Q_{rxn} + Q_{rev} + Q_{ohm}
\]

with the boundary conditions determined by Newton’s cooling law:

\[
-\lambda \frac{\partial T}{\partial x} \bigg|_{x=0} = h(T_\infty - T)
\]

\[
-\lambda \frac{\partial T}{\partial x} \bigg|_{x=L_0 + L_p + L_s} = h(T - T_\infty)
\]

where \( h \) is the heat transfer coefficient, \( T_\infty \) is the environmental temperature, \( Q_{rxn} \) is the total reaction heat generation rate, \( Q_{rev} \) is the total reversible heat generation rate, \( Q_{ohm} \) is the total ohmic heat generation rate. The heat fluxes are defined by:

\[
Q_{rxn} = FaJ_i (\phi_1 - \phi_2 - U)
\]

\[
Q_{rev} = FaJ_i \frac{dU}{dT}
\]

\[
Q_{ohm} = \sigma \frac{\partial \phi_1}{\partial x} \frac{\partial \phi_1}{\partial x} + \kappa \frac{\partial \phi_2}{\partial x} \frac{\partial \phi_2}{\partial x} + \frac{2 \kappa \sigma RT}{F} (1 - t_i) \frac{\partial \ln C}{\partial x} \frac{\partial \phi_2}{\partial x}
\]

The temperature dependent open circuit potential of electrode \( i \) is approximated by Taylor’s first order expansion around a reference temperature:

\[
U_i = U_{i,ref} + (T - T_{ref}) \left[ \frac{dU_i}{dT} \right]_i
\]

where \( U_{i,ref} \) is the open circuit potential under the reference temperature \( T_{ref} \).

3. The COMSOL Multiphysics (MP) 3.5a model

The mathematical model described in Section 2 is a multi-scale model. We developed several geometries using this software: a 1D geometry which consists of three sequentially connected lines to represent the positive electrode, the separator and the negative electrode, respectively, a 2D geometry which consists of two rectangles to denote the solid phase in the electrodes. The geometries are shown in Fig. 2. The vertical coordinate in the 2D geometry indicates the radial direction of the solid particles. Since we ignore the diffusion of Li ions in the \( x \)-direction in the particle, the corresponding diffusion coefficient is set to zero in this direction. The concentration of the binary electrolyte, the potential in the electrolyte, the potential in the solid phase and the pore wall flux are solved in the 1D geometry. The concentration of Li ions in the solid phase is solved in the 2D geometry. The pore wall flux is extruded from the 1D domain and projected to the top boundary of the 2D geometry by using “subdomain extrusion coupling variables” in COMSOL Multiphysics. The concentration of Li ions on the top boundary in the 2D geometry is projected to the 1D domain by using “boundary extrusion coupling variables”.

The thermal behavior of the Li ion battery during pulse discharge is also simulated in COSMOL Multiphysics. The battery is discharged for 3000 s at C/2 rate first and then discharged at C rate until the cell voltage drops to 2.5 V. The change of the applied current density is also simulated in COSMOL Multiphysics. The battery is discharged for 3000 s at C/2 rate first and then discharged at 3 C rate until the cell voltage drops to 2.5 V. The change of the applied current density is shown in Fig. 5. The cell provides more discharge capacity when it is placed in a better heat isolation environment (i.e. adiabatic condition). In a better isolated environment, the cell temperature increases faster during the 1 C discharge process which results in the higher diffusion coefficient for the binary electrolyte and reduces the diffusion limitations.

The reduction of the diffusion limit in the binary electrolyte can be verified by comparing the concentration profile of the electrolyte under different cooling conditions. Fig. 6 shows the concentration profiles of the electrolyte at the end of 1 C discharge process under the two limiting conditions. The concentration profile under the adiabatic condition is flatter than that in the isothermal case, which indicates a better diffusion property in the electrolyte under the adiabatic condition than under the isothermal condition.

Fig. 5. Cell voltage for 1 C discharge process under different cooling conditions.

Fig. 6. Comparison of the concentration profiles of the binary electrolyte at the end of the 1 C discharge process under the isothermal condition and the adiabatic condition.

Fig. 7. Temperature on the cell surface during discharge process under different current rates while the heat transfer coefficient \( h = 1.0 \text{ Wm}^{-2}\text{K}^{-1} \) where the DOD is defined as: \( \text{DOD} = \text{time} \times \text{C rate} / 3600 \).

Fig. 8. Cell voltage during the \( \text{C}/2 \) discharge for 3000 s followed by a 3 C pulse discharge until the cell voltage drops to 2.5 V. The corresponding temperature
Fig. 8. Cell voltage at C/2 discharge for 3000 s followed by a 3 C pulse discharge.

Fig. 9. Temperature on the cell surface in the discharge process with 3 C pulse.

Fig. 10. Concentration of the binary electrolyte at the two ends of the cell (the bottom line is at x = 0, the top line is at x = 1.65 × 10^{-4} m) in the C/2 discharge process with a 3 C pulse. Mathematical modeling of a lithium ion battery with thermal effects in COMSOL.

The beginning of the pulse, the concentration of the electrolyte changes extremely, after that it relaxes and tend to a stable value.

5. Conclusions

The thermal behavior of a lithium ion battery during galvanostatic discharge w/o pulse can be predicted by using COMSOL Multiphysics (MP) 3.5a. Though better thermal isolation environment improves the discharge capacity, the higher cell temperature raises the risk of thermal runaway and more rapid degradation of the cell.
